[Received 23 May 2012, revised 7 December 2012, accepted 11 April 2013]

Ductal carcinoma *in situ* (DCIS) lesions are non-invasive tumours of the breast which are thought to precede most invasive breast cancers (IBC). As individual DCIS lesions are initiated, grow and invade (i.e. become IBC) the size distribution of the DCIS lesions present in a given human population will evolve. We derive a differential equation governing this evolution and show, for given assumptions about growth and invasion, that there is a unique distribution which does not vary with time. Further, we show that any initial distribution converges to this stationary distribution exponentially quickly. It is therefore reasonable to assume that the stationary distribution governs the size of DCIS lesions in human populations which are relatively stable with respect to the determinants of breast cancer. Based on this assumption and the size data of 110 DCIS lesions detected in a mammographic screening program between 1993 and 2000, we produce maximum likelihood estimates for certain growth and invasion parameters. Assuming that DCIS size is proportional to a positive power p of the time since tumour initiation, we estimate p to be 0.50 with a 95% confidence interval of $(0.35, 0.71)$. Therefore we estimate that DCIS lesions follow a square-root growth law and hence that they grow rapidly when small and relatively slowly when large. Our approach and results should be useful for other mathematical studies of cancer, especially those investigating biological mechanisms of invasion.

Keywords: Breast cancer, cancer progression, DCIS, population dynamics, maximum likelihood

1. Introduction

Most breast cancers arise in the epithelial cells which line the milk ducts of each breast (Erbas *et al.* (2006); Silverstein *et al.* (2006)). While a tumour remains confined to the system of ducts it is known as a *ductal carcinoma in situ* (DCIS) of the breast. If the tumour penetrates the epithelial membrane which bounds the ductal system then it is termed an *invasive breast cancer* (IBC). In this paper we will use the term *tumour* to mean either DCIS or IBC and we use *DCIS lesion* or simply *lesion* as a synonym for DCIS. IBCs are considered to be life-threatening whereas DCIS lesions *per se* are not, since the

epithelial membrane prevents DCIS lesions from spreading to critical organs.

The transition from DCIS to IBC is known as *invasion*. It is not known what biological events trigger invasion or what proportion of DCIS lesions would invade if left untreated because essentially all DCIS lesions are surgically removed once discovered. However, as this surgery can be psychologically and physically damaging and could potentially spread cancerous cells, determining the risk associated with untreated DCIS is of great clinical importance.

Currently it is not ethically possible to directly observe the natural history of DCIS (though see Welch *et al.* (2008)) so our knowledge comes from indirect sources: follow-up studies of DCIS initially misdiagnosed as benign; studies of recurrence of DCIS as invasive cancer; autopsy studies; studies of risk factors for DCIS; animal studies; and mathematical studies (Erbas *et al.* (2006)). As Erbas *et al.* (2006) point out, all of these studies have weaknesses for estimating the proportion of DCIS lesions which invade, e.g. lesions observed in follow-up studies are likely to be of low histological grade and consequently less prone to invasion than other DCIS lesions. In this context, a mathematical study of DCIS, despite its reliance on simplifying assumptions, may be able to make an important contribution to the ongoing debate (Welch *et al.* (2008)) about the clinical significance of DCIS.

Previous mathematical studies of breast cancer have generally focussed on IBC. Some of these studies do not incorporate any DCIS phase (Atkinson *et al.* (1983); Hart *et al.* (1998)) while others include a DCIS phase only as a period of latency between tumour initiation and the start of invasive growth (Kopans *et al.* (2003); Moolgavkar & Luebeck (2003); Yakovlev *et al.* (1996)). By contrast, the present paper is chiefly concerned with DCIS. Franks *et al.* (2005) also explicitly study DCIS though their approach is very different to the one presented here. Dewanji *et al.* (1989) use a general two-stage model of cancer growth and progression to derive interesting results which are applicable to DCIS, though their approach is also very different from the one presented here, being based on stochastic processes rather than differential equations and with age rather than calendar time as the time variable.

DCIS *size* is defined as the maximal linear extent of the lesion, or its diameter. While volume is often used to describe the size of IBCs, the linear or branched shape of DCIS makes this definition impractical (Silverstein *et al.* (2006)).

The rest of this paper is set out as follows. In §2 we use the results of Diekmann *et al.* (1984) and the example of Hart *et al.* (1998) to give an equation governing the time-evolution of the DCIS size distribution of a given human population as individual lesions grow and invade. For given assumptions about growth and invasion there is a unique *stationary distribution* which does not vary with time. Further, we prove (in §3) that any initial DCIS size distribution converges to this stationary distribution exponentially quickly. Therefore, for a human population which is relatively stable with respect to the determinants of breast cancer, it is reasonable to assume that the stationary distribution is close to the true DCIS size distribution. We use this assumption in §4 and §5 to generate maximum likelihood estimates for certain DCIS growth and invasion parameters, based on data from a mammographic screening program. In §6 we draw some conclusions and finish with some ideas for future research.

2. The stationary distribution of DCIS size

In this section we find an equation governing the evolution of the size distribution of DCIS lesions present in a human population as individual lesions are initiated, grow and invade. For given growth and invasion rates there is a unique *stationary distribution* which does not vary with time and we give an expression for this distribution. As mentioned above, this section is based on the results of Diekmann *et al.* (1984) and motivated by the ideas of Hart *et al.* (1998).

Diekmann *et al.* (1984) derive an equation governing the time-evolution of the size distribution of a population of cells which grow, die and reproduce by binary fission. Setting the fission rate to zero gives an equation describing the size distribution of a population of individuals which grow and stochastically leave the population, so this applies to a population of DCIS lesions which grow and invade. Here we assume that DCIS lesions invade and grow independently of each other, even if they occur in the same woman. This assumption is only approximately true, but multiple (detectable) DCIS lesions per woman seem to be very rare so this assumption probably has a similar level of validity to the independence assumptions of most practical statistics.

So following Diekmann *et al.* (1984), though using slightly different notation, we assume that individual DCIS lesions of size x grow and invade at rates $f(x)/\alpha$ and $\mu(x)$, respectively, where the *growth factor* $\alpha > 0$ is constant for each tumour. Hence the size $y(\tau)$ of a DCIS lesion at time τ evolves according to the differential equation

$$\frac{dy}{d\tau} = \frac{1}{\alpha} f(y) \tag{2.1}$$

and if X is a random variable giving the tumour size at invasion (conditional on α) then $Pr(X > x)$ is

$$G(x) = \exp\left(-\int_0^x \frac{\mu(\xi)\alpha}{f(\xi)}\, d\xi\right) \tag{2.2}$$

(*cf.* (2.4) of Diekmann *et al.* (1984)). The function f determines the DCIS growth law and we assume it is such that any solution $y : [0,\infty) \to \mathbb{R}$ of (2.1) with $y(0)$ approximately the size of one epithelial cell is a strictly monotonically increasing function. For the rest of this section we treat the growth factor α as a constant but in later sections we will allow it to vary randomly from tumour to tumour.

Now, let $\phi(x,t)$ be an (unnormalized) density function for the DCIS lesions in the population, i.e. suppose that ϕ is such that $\int_0^x \phi(\xi,t)\, d\xi$ is the expected number of lesions at time t with size in the range $[0,x]$, for any $x > 0$ and t. Then applying equation (2.1) of Diekmann *et al.* (1984) to our situation (where the fission rate b is zero) gives

$$\frac{\partial\phi}{\partial t} + \frac{\partial}{\partial x}\left(\frac{\phi f}{\alpha}\right) = -\mu\phi. \tag{2.3}$$

So far we have not accounted for the process of tumour initiation. However a straight-forward modification of the argument in the Appendix of Diekmann *et al.* (1984) shows that if tumours of size x are initiated at a rate $S(x)$, assumed constant in time, then ϕ will evolve according to

$$\frac{\partial\phi}{\partial t} + \frac{\partial}{\partial x}\left(\frac{\phi f}{\alpha}\right) = -\mu\phi + S. \tag{2.4}$$

Note that $S(x)$ is the rate of initiation with respect to calendar time, not age, so our assumption that $S(x)$ is independent of time is roughly equivalent to the assumption that the number of DCIS lesions which are initiated in the human population is the same from month to month. The source term S is unknown but since DCIS lesions are initially approximately the size of one epithelial cell we know that $S(x) = 0$ for all $x > \varepsilon$ where $\varepsilon > 0$ is microscopically small.

Using (2.2) to write μ in terms of G we arrive at the following inhomogenous linear equation governing the time-evolution of ϕ:

$$\frac{\partial\phi}{\partial t} + \frac{f}{\alpha}\frac{\partial\phi}{\partial x} + \left(\frac{f'}{\alpha} - \frac{fG'}{\alpha G}\right)\phi = S. \tag{2.5}$$

Now, let ψ be the *unnormalized stationary distribution*, meaning that it satisfies (2.5) and is a function of x only, i.e. $\partial\psi/\partial t = 0$. Then for all macroscopic x, (2.5) becomes

$$0 = \psi \frac{f}{\alpha}\left(-\frac{\psi'}{\psi} - \frac{f'}{f} + \frac{G'}{G}\right)$$

where the primes denote differentiation with respect to x. This has the unique solution

$$\psi(x) = c\,\frac{G(x)}{f(x)} \tag{2.6}$$

where c is a constant. If c is chosen so that $\int_0^\infty \psi(x)\,dx = 1$ then we refer to ψ as the (normalized) *stationary distribution*.

3. Convergence to the stationary distribution

In §2 we used the results of Diekmann *et al.* (1984) to show that, for given growth and invasion rates, there is a unique DCIS size distribution which does not vary with time. Unfortunately the convergence results of Diekmann *et al.* (1984) cannot be directly applied to our situation of continuous tumour initiation and zero fission rates (*cf.* the assumptions H_b on page 229 of Diekmann *et al.* (1984)). Therefore, in this section we prove that any distribution converges to the stationary distribution exponentially quickly (and with a reasonable time-scale). This result adds legitimacy to our use of the stationary distribution in §5 to produce maximum likelihood estimates of DCIS growth and invasion parameters. However the proof is fairly technical and a reader who is prepared to accept this result can skip this section without compromising his or her understanding of the later sections.

We now fix a value of α for the rest of this section and we use the notation of §2 throughout except that we write ϕ_x and ϕ_t for the partial derivatives of ϕ. In this notation, (2.5) becomes

$$\phi_t + \left(\frac{f}{\alpha}\right)\phi_x + \left(\frac{f'}{\alpha} - \frac{fG'}{\alpha G}\right)\phi = S. \tag{3.1}$$

We will show that for any function ϕ which satisfies (3.1), the sequence of functions $\phi(\cdot,t)$ converges to the unnormalized stationary distribution ψ as $t \to \infty$. The proof will be given for the model of invasion used in §4 and §5, where $\mu(x) = h$ is constant, but the proof extends to other models without major modifications.

It follows from (3.1) that $\delta \overset{\text{def}}{=} \phi - \psi$ satisfies the homogenous partial differential equation

$$\delta_t + \left(\frac{f}{\alpha}\right)\delta_x + \left(\frac{f'}{\alpha} - \frac{fG'}{\alpha G}\right)\delta = 0. \tag{3.2}$$

Our aim is to show that $\delta(\cdot,t)$ approaches 0 as $t \to \infty$. Since (3.2) is a linear, first-order partial differential equation we can solve this equation by the method of characteristics (e.g. see John (1978) pages 8–14). The graph

$$\{(x,t,z) \in \mathbb{R}^3 \mid z = \delta(x,t)\}$$

of a solution δ of (3.2) is known as an *integral surface*, and the images of the integral curves of the vector field

$$\left(\frac{f(x)}{\alpha}, 1, \frac{zf(x)G'(x)}{\alpha G(x)} - \frac{zf'(x)}{\alpha}\right) \tag{3.3}$$

are the *characteristic curves* of (3.2). The projection of a characteristic curve into the xt-plane is called a *characteristic*. Our interest in the characteristic curves derives from the fact that every integral surface is a union of characteristic curves (John (1978)).

Now, let $\delta_0 : \mathbb{R}_{>0} \to \mathbb{R}$ be given, where $\mathbb{R}_{>0}$ denotes the positive reals. From now on we let δ denote the solution of (3.2) which satisfies the initial conditions $\delta(\xi, 0) = \delta_0(\xi)$ for every $\xi > 0$. Let $(x,t) \in \mathbb{R}_{>0} \times \mathbb{R}$ be given and assume for the rest of this section that y is the solution of (2.1) with $y(t) = x$. The characteristic which passes through the point (x,t) is the graph of y, i.e. the characteristic is the trajectory of a tumour which is of size x at time t. If the characteristic does *not* meet the positive x-axis then the initial conditions above do not determine $\delta(x,t)$. In this case we set $\delta(x,t) = 0$ since no tumour in existence at time 0 has size x at time t and there is no source term in (3.2). On the other hand, if the characteristic through (x,t) meets the positive x-axis then the initial conditions determine $\delta(x,t)$ as follows.

It is easily checked that any integral curve γ of (3.3) is given by

$$\gamma(\tau) = \left(Y(\tau + t_0), \tau + t_0, z_0 \frac{f(x_0)G(Y(\tau + t_0))}{G(x_0) f(Y(\tau + t_0))} \right) \tag{3.4}$$

for some $x_0, t_0, z_0 \in \mathbb{R}$ where the function Y solves (2.1) with $Y(t_0) = x_0$. However, since the corresponding characteristic curve (i.e. the image of γ) does not depend on t_0 we may assume without loss of generality that $t_0 = 0$. Suppose now that the image of γ is the characteristic curve which passes through $(x, t, \delta(x,t))$. This implies firstly that $Y(t) = x$ and hence $Y = y$ and secondly that γ lies in the integral surface of δ, so from $\gamma(0) = (x_0, 0, z_0)$ we have $z_0 = \delta_0(x_0)$. Combining this with (3.4) gives

$$\delta(x,t) = \delta_0(I(x,t)) \frac{G(x)}{G(I(x,t))} \frac{f(I(x,t))}{f(x)} \tag{3.5}$$

where we have written $I(x,t)$ in the place of x_0 to make its dependence on x and t explicit. Here $I(x,t)$ is the initial size of a tumour which is of size x at time t, i.e. $I(x,t)$ is the function of x and t which is determined by the condition $I(x,t) = y(0)$ where, as above, y solves (2.1) with $y(t) = x$.

As in §4 we assume that the time between tumor initiation and invasion is a random variable T with constant hazard h, i.e. that $Pr(T > t) = \exp(-ht)$. Let X be the tumour size at invasion and recall that $G(\xi) = Pr(X > \xi)$. Then for a tumour which was initiated at time a, $X = y(T + a)$ and so

$$G(\xi) = Pr(X > \xi) = Pr(y(T+a) > \xi) = Pr(T > y^{-1}(\xi) - a) = \exp(-h(y^{-1}(\xi) - a)).$$

This is consistent with (4.4) because $a = 0$ in §4. Therefore, regardless of the value of a,

$$\frac{G(x)}{G(I(x,t))} = e^{-ht}. \tag{3.6}$$

Now, from (2.1) we have

$$t/\alpha = \int_0^t \frac{d\tau}{\alpha} = \int_{I(x,t)}^x \frac{d\xi}{f(\xi)} = F(x) - F(I(x,t))$$

where F is any function which satisfies $F' = 1/f$. This equation holds for arbitrary x and t so taking partial derivatives with respect to x and rearranging gives

$$\frac{f(I(x,t))}{f(x)} = \frac{\partial I}{\partial x}(x,t). \tag{3.7}$$

So by combining (3.5), (3.6) and (3.7) we obtain

$$\int_0^\infty |\delta(\xi,t)|d\xi = e^{-ht}\int_0^\infty |\delta_0(\iota)|d\iota. \tag{3.8}$$

This shows that the functions $\delta(\cdot,t)$ approach 0 exponentially quickly with respect to the L^1 norm as $t \to \infty$. Therefore any DCIS size distribution approaches the stationary distribution exponentially quickly as $t \to \infty$.

Since h is the hazard of invasion, the time-scale of convergence to the stationary distribution is comparable to the time for an individual DCIS lesion to invade, perhaps of the order of 20 years. Hence the rate of convergence is comparable to the rate of population changes which affect the incidence of breast cancer such as changes to the distributions of: age at first birth; age at menarche; pre- and post-menopausal body-mass index; and exogenous hormone use. So in human populations where the determinants of breast cancer have changed slowly in recent years, we would expect the population DCIS size distribution to track with the changes in the underlying stationary distribution without ever deviating too far from it.

The above arguments are conditional on α, however since the rate of convergence in (3.8) does not depend on α, the same convergence results apply when we marginalize over α as in the next section.

4. Parametric assumptions

In §5 we will use the method of maximum likelihood to estimate certain important features of DCIS growth and invasion. As for most likelihood-based estimation procedures we must first make some parametric assumptions. In this section we describe these assumptions and give an explicit expression for the corresponding stationary distribution.

Hart *et al.* (1998) show that the invasive breast cancers cannot grow according to exponential, logistic or Gompertz laws, but can grow according to a power law. Following this work, we assume that DCIS size is proportional to a positive power of the time since tumour initiation. This corresponds to the choice

$$f(y) = ky^{\beta} \tag{4.1}$$

in (2.1) where $k > 0$ and $\beta < 1$ are constants. Then (2.1) has the solution

$$y(t) = [kt(1-\beta)/\alpha + x_0^{1-\beta}]^{\frac{1}{1-\beta}} \tag{4.2}$$

where x_0 is the initial size of the DCIS lesion (see equation (2) of Hart *et al.* (1998)). Therefore the inverse of y is given by $y^{-1}(x) = [x^{1-\beta} - x_0^{1-\beta}]\alpha/(k(1-\beta))$. Assuming that x_0 is negligibly small compared to x (which is reasonable, since x_0 is approximately the size of one epithelial cell) we have

$$y^{-1}(x) = \frac{\alpha x^{1-\beta}}{k(1-\beta)}. \tag{4.3}$$

Now, as in §2, let X be a random variable representing tumour size at invasion conditional on the growth factor α and define $G(x) = Pr(X > x)$. Let T be the time from tumour initiation to invasion conditional on α, i.e. $T = y^{-1}(X)$ where y^{-1} is as given in (4.3). We model invasion by one of the simplest assumptions possible in our framework, namely that the hazard function for T is some constant $h > 0$, i.e. that

$$Pr(t \leqslant T < t + \Delta t \mid t \leqslant T) = h\Delta t + O(\Delta t^2),$$

so $Pr(T > t) = \exp(-ht)$. Combining this with $G(x) = Pr(T > y^{-1}(x))$ gives

$$G(x) = \exp\left[-hy^{-1}(x)\right]. \tag{4.4}$$

Substituting (4.3) into (4.4) then substituting the result into (2.6) gives an expression for the stationary distribution ψ_α conditional on α:

$$\psi_\alpha(x) = c_\alpha x^{-\beta} \exp\left[\frac{-h\alpha x^{1-\beta}}{k(1-\beta)}\right] \tag{4.5}$$

where c_α does not depend on x. The integral $\int_0^\infty \psi_\alpha(x)dx$ exists for $\beta < 1$ and substituting (4.5) into the equation $\int_0^\infty \psi_\alpha(x)dx = 1$ and effecting a simple change of variables shows

$$c_\alpha = \alpha h/k.$$

Now, as in Brown *et al.* (1984) we take the growth factor α to be exponentially distributed. Due to the presence of k in (4.1) we may assume without loss of generality that the expected value of α is 1. Marginalising (4.5) over α gives the PDF of the (unconditional) stationary distribution:

$$\begin{aligned}\psi(x) &= \int_0^\infty e^{-\alpha}\psi_\alpha(x)d\alpha \\ &= x^{-\beta}hk^{-1}\int_0^\infty \alpha \exp\left[-\alpha\left(\frac{hx^{1-\beta}}{k(1-\beta)}+1\right)\right]d\alpha \\ &= x^{-\beta}kh^{-1}\left[kh^{-1}+x^{1-\beta}(1-\beta)^{-1}\right]^{-2} \qquad (4.6)\end{aligned}$$

where the last step uses integration by parts.

5. Comparison with mammography data

In §3 we showed that any DCIS size distribution approaches the stationary distribution exponentially fast (and on a relatively short time-scale). Therefore it seems reasonable to assume that the size distribution of DCIS lesions present in a real human population will approximate the stationary distribution corresponding to the processes of growth and invasion in operation. In this section we use this assumption, together with the parametric assumptions of §4, to obtain maximum likelihood estimates for the growth and invasion parameters introduced in §4. This estimation will be based on DCIS size data collected by a mammographic screening program operated by BreastScreen Victoria (BSV), in Victoria, Australia since 1993.

5.1 *The BSV dataset*

The BreastScreen Victoria (BSV) data was collected between 1993 and 2000. In the Australian state of Victoria, women are invited to attend free breast screen clinics every 2 years between the ages of 50 and 69 years. We restricted our data to this age range and to DCIS lesions which were detected via a woman's first mammogram. The ages at first mammogram were approximately uniformly distributed across this age range. The size of a DCIS lesion was measured by a pathologist after it was detected via a mammogram and surgically removed. Most DCIS lesions are roughly linear in shape, and for such lesions, DCIS size is essentially the length of the lesion.

Since very few pre-invasive breast cancers are detected outside of mammographic screening programs, the BSV dataset is an excellent source of data on larger DCIS lesions. However, detection of a small DCIS lesion via mammographic screening is uncertain, and probably depends on a number of factors such as the orientation of the lesion, its position in a dense or non-dense part of the breast and the presence or absence of micro-calcification (Silverstein *et al.* (2006)). Therefore, in order to avoid these complications, we restricted the BSV data to those lesions with size greater than or equal to 15mm (though see §5.3). We also excluded two outlying DCIS lesions with size greater than 100mm. This gave us a dataset of 110 DCIS lesions of size at least 15mm which were detected on a woman's first mammogram when she was between 50 and 69 (inclusive) years old. A histogram of these sizes is given in Figure 1. The 25%, 50% and 75% quartiles for these sizes were 18, 24, and 35mm, respectively, while the age of participants had a mean of 58 years and a range of 50 to 69 years.

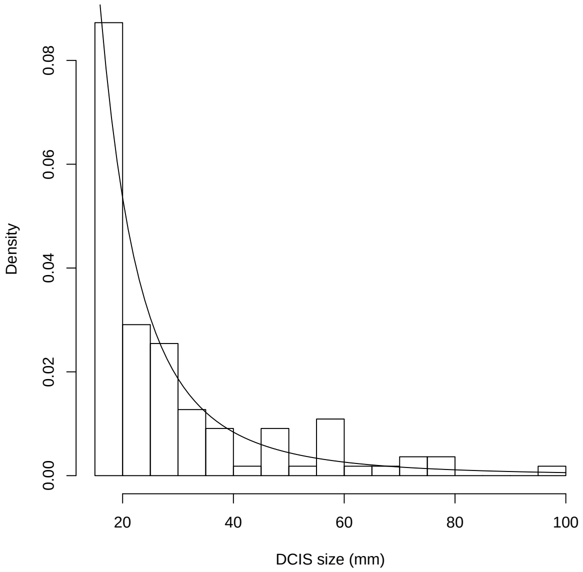

FIG. 1. A histogram of DCIS size in the BSV dataset, with the fitted DCIS size distribution overlaid

5.2 *Maximum likelihood estimates*

We would now like to use the PDF (4.6) of the stationary distribution to obtain maximum likelihood estimates. However since we have restricted the BSV data to tumours with size greater than or equal to 15mm we must first condition this PDF appropriately. A simple change of variables shows

$$\begin{aligned}\int_{15}^{\infty} \psi(x)dx &= \int_{15}^{\infty} x^{-\beta} kh^{-1} \left[kh^{-1} + x^{1-\beta}(1-\beta)^{-1}\right]^{-2} dx \\ &= \left[1 + \frac{15^{1-\beta}}{kh^{-1}(1-\beta)}\right]^{-1}\end{aligned}$$

so the appropriate PDF for the BSV data is

$$\left[1+\frac{15^{1-\beta}}{kh^{-1}(1-\beta)}\right]\frac{x^{-\beta}kh^{-1}}{\left[kh^{-1}+x^{1-\beta}(1-\beta)^{-1}\right]^{2}}. \tag{5.1}$$

Note that h and k only appear in (5.1) in the combination kh^{-1}. Therefore it is not possible to produce separate maximum likelihood estimates for the parameters h and k, only for the quantity $\theta \overset{\text{def}}{=} kh^{-1}$. Therefore we define the following likelihood function

$$L(\beta,\theta)=\prod_{i=1}^{110} x_i^{-\beta}\frac{[\theta+15^{1-\beta}(1-\beta)^{-1}]}{[\theta+x_i^{1-\beta}(1-\beta)^{-1}]^2} \tag{5.2}$$

where $x_1, x_2, \ldots, x_{110}$ are the sizes (in millimeters) of the DCIS lesions in the BSV dataset.

We re-parameterized the likelihood (5.2) in terms of β and $\log\theta$ then calculated maximum likelihood estimates using the ‘mle’ function of R 2.11.1 (R Development Core Team (2006)). The corresponding estimates for β and θ are

$$(\hat{\beta},\hat{\theta})=(-0.99,30.9).$$

The PDF (5.1) corresponding to these estimates is overlaid on the histogram of the BSV data in Figure 1, showing a good fit.

We generated conservative 95% confidence intervals (95% CI) for β and θ by projecting the region of the parameter space where the relative log-likelihood is greater than -5.99 onto the β and θ co-ordinate axes (see §4.5 of Severini (2000)). This gave a 95% CI of $(-1.70,-0.48)$ for β and $(0.00,1278)$ for θ.

5.3 *Sensitivity analysis*

We varied the size cutoff, introduced because of the uncertain detection of small lesions, in order to assess its impact on our estimates. Conditioning on DCIS size greater than or equal to 10mm, 15mm or 20mm gave approximately the same estimates for β, as can be seen from Table 1.

5.4 *Interpretation of the results*

The confidence interval for θ is so wide that we cannot draw any conclusions regarding the growth or invasion rates of DCIS lesions. However the estimate for β is more reliable. By (4.2) our estimate $\hat{\beta}=-0.99$ corresponds, to a good approximation, to DCIS growth in which the lesion size is proportional to the square root of the time since tumour initiation. The bounds of the 95% CI place the exponent

Table 1. Results of a sensitivity analysis in which the size cutoff is varied

Cutoff (mm)	Number of DCIS lesions	$\hat{\beta}$ (95% CI)	$\hat{\theta}$ (95% CI)
10	155	-1.07 (-1.70, -0.47)	86 (5.9, 661)
15	110	-0.99 (-1.86, -0.41)	31 (0.00, 1278)
20	77	-1.06 (-2.13, -0.55)	0.41 (0.00, 4357)

between 0.35 and 0.71, corresponding to a class of curves with similar, very rapid initial growth which then slows with increasing time and DCIS size.

This may be biologically plausible for two reasons: (1) unlike large lesions, small lesions are unconstricted by the epithelial membrane and surrounding tissues which bound the milk-ducts; and (2) it may be that large lesions receive less nutrients per cell than small ones due to limited contact with the epithelial membrane (Franks *et al.* (2005)).

Even if the assumption of a power-law for growth is overly restrictive, our results still suggest that DCIS growth slows down as the lesion increases in size, in contrast to IBC which grows at an increasing rate (Hart *et al.* (1998)).

A square-root growth function may also be the key to explaining a surprising feature of the BSV data. The size distribution for DCIS lesions detected on a woman's first mammographic screening is remarkably similar to the size distribution for tumours detected on a subsequent screen (see Figure 2). This is surprising because first-screen-detected tumours could have been growing for more than 20 years while subsequent-screen-detected tumours can only have been present and of a detectable size for 2 years (the usual time between screens). Our estimate that DCIS growth is initially very rapid and then relatively slow may help to explain this feature. Note that the estimates of §5.2 were only based on the size data of DCIS lesions detected on the first screen.

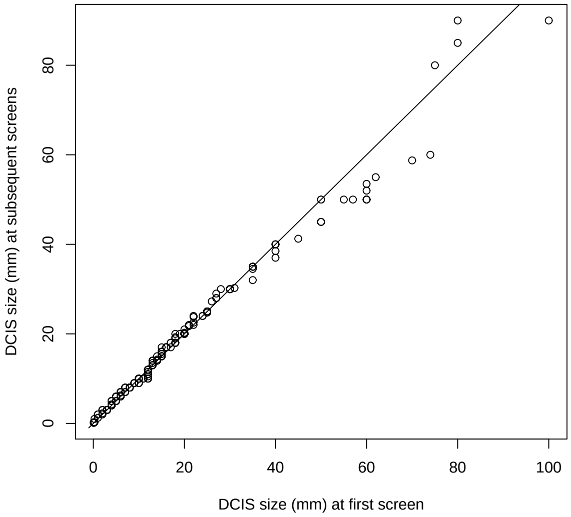

FIG. 2. A quantile-quantile plot comparing the DCIS size distributions of lesions which are detected on a woman's first mammographic screening with those which are detected on a subsequent screen.

6. Conclusions and future research

Because the natural history of DCIS cannot ethically be observed, indirect studies of DCIS growth and invasion such as the present one are needed to resolve the controversies surrounding the clinical significance of DCIS. The main contribution of our paper to this debate is our estimate that DCIS lesions approximately obey a square-root growth function and that they grow rapidly when small and relatively slowly when large. However, we have also shown how the unobserved processes of DCIS growth and invasion affect the observed DCIS size distribution, and we hope that this approach will also be useful for future studies of DCIS.

A limitation of our approach is that, unlike stochastic models like that of Dewanji *et al.* (1989), our model does not allow for the possibility of DCIS regression. In theory, regression seems possible, though we are not aware of any data to support this hypothesis so the notion of DCIS regression remains fairly controversial. Another limitation is that we have ignored the possibility that DCIS lesions might leave the population due to migration or death of the host, in addition to invasion. However, our estimates were based on women aged 50 to 69 years, who have reasonably low mortality rates, so we don't expect this to affect our estimates greatly.

A more serious limitation is that, due to the form of the likelihood function, it is impossible to produce separate estimates for the rates of DCIS growth and invasion (see §5.2). However, it might be possible to overcome this limitation by incorporating information on DCIS lesions which are detected at a woman's second or later mammographic screening. Without such an extension, even with a larger dataset, it is probably not possible to use our approach to estimate the proportion P of DCIS lesions which will invade within a lifetime. This proportion is of great clinical importance because if it is very small then the current treatment regime of mandatory removal may be causing more harm than good, as suggested recently (Welch *et al.* (2008)). In any case, we hope that our estimate of the DCIS growth law will be used in other mathematical studies of DCIS and that one of these will produce credible estimates for P.

Another possible use of our approach is as a test on competing theories of invasion. At present, the biological events which trigger invasion are not known, however different biological invasion mechanisms will generally give different forms for the distribution of DCIS size at invasion. For example, if it is assumed that invasion occurs when a DCIS lesion grows along a milk duct to a pre-existing 'hot spot' (which might be a weakness in the epithelial membrane or a mutant stromal cell) then rather than (4.4) we would have $G(x) = \exp(-hx)$ for some constant $h > 0$. It may therefore be possible to use the methods of this paper to test different biological theories of invasion by computing maximum likelihood estimates and comparing the parsimony of the different models using a measure such as the Bayesian information criterion.

Acknowledgements

We would like to acknowledge and thank BreastScreen Victoria for the provision of data and the US Department of Defense Breast Cancer Concept Award (DAMD 17-03-0687) which funded aspects of this work.
